ABSTRACT

Background: Ramadan fasting as a pivotal Islamic practice can profoundly affect dietary habits, physical activity, and overall lifestyle. This study investigated the impact of Ramadan fasting during the COVID-19 lockdown on perceived weight changes and lifestyle modifications among Muslims globally. This study was undertaken to assess the influence of Ramadan fasting and lockdown restrictions on weight perception and lifestyle changes, including dietary patterns and physical activity levels, across a diverse multinational sample.

Methods: A cross-sectional multicenter observational study was conducted involving 21,657 adult Muslims from 20 countries during Ramadan 2020. Data were collected via a comprehensive electronic questionnaire covering dietary intake, physical activity, sleep patterns, and self-reported weight changes.

Results: The analysis indicated significant lifestyle and dietary adjustments during Ramadan under lockdown. Participants reported shifts towards healthier eating, with increased fruit, vegetable, and home-cooked meal consumption. However, challenges such as reduced physical activity and increased intake of fried and sugary foods were noted. Marital status, age, and a family history of obesity were significant determinants of weight changes.

Conclusion: Despite the pandemic's constraints, individuals adapted their lifestyles during Ramadan fasting, reflecting the resilience of dietary and physical activity behaviors. The study highlights the complex relationship between religious fasting, health, and pandemic-related lifestyle disruptions, emphasizing the need for context-specific nutritional and health guidance.

Introduction

The observance of Ramadan, the ninth month of the Islamic calendar, entails fasting from dawn to sunset, a practice engaged in by about 1.5 billion Muslims worldwide. This religious mandate, one of the five pillars of Islam, necessitates complete abstinence from food, drink, and other physical needs during daylight hours (1). The significance of Ramadan extends beyond spiritual purification, influencing various aspects of daily life, including dietary habits and nutritional composition, physical activity, and lifestyle behaviors including sleep habits (2-4). As the Islamic calendar is lunar based, the timing of Ramadan shifts annually and thereby the fasting duration varies across different geographical locations and seasons. This variability presents a unique opportunity to study the impact of Ramadan intermittent fasting on human health and behavior in a naturalistic setting.

An emerging research underscored the multifaceted effects of Ramadan intermittent fasting (RIF) on health parameters, including metabolic changes, weight regulation, and psychological well-being (5). Notably, RIF has been associated with improvements in cardiovascular health, insulin sensitivity, liver functions, and lipid profiles, alongside modifications in body weight and composition (1, 6-10). However, the literature reveals a complex picture, with factors such as dietary quality, sleep patterns, and physical activity levels during Ramadan that significantly influence the outcomes (11).

The COVID-19 pandemic has led to unprecedented global health responses, including stringent social distancing measures, lockdowns, and quarantines. These interventions, aimed at curtailing the spread of the virus, could significantly influence the public health, alter the access to healthcare, modify the physical activity levels, and impact the dietary habits across populations. The variability in these impacts highlights the need to explore how such global health crises affect weight and lifestyle behaviors, especially during periods of restrictive living conditions (12-15). The intersection of these pandemic-related restrictions with the observance of Ramadan, a period of intermittent fasting practiced by Muslims worldwide, presents a unique opportunity to examine lifestyle and weight changes. Ramadan fasting traditionally encourages healthier eating habits, enhanced self-discipline, and a focus on spiritual growth, which could counteract the negative lifestyle changes that lockdowns induce. However, the comprehensive effects of combined pandemic restrictions and fasting during Ramadan on weight and lifestyle remain underexplored

globally (16).

This multicentric study was undertaken to address this gap by investigating the influence of Ramadan fasting alongside pandemic-induced lockdowns on perceived weight and lifestyle changes. It aimed to provide a global perspective by analyzing data from multiple countries, offering insights into how these dual factors influence health behaviors and weight management. The research identified the preventive and contributory factors to weight change and informing public health strategies for managing health and lifestyle during concurrent religious observance and global health crises.

Materials and Methods

In a cross-sectional observational framework investigation scrutinized the effects of RIF on lifestyle and dietary modifications among adults Muslims during the COVID-19 outbreak. A detailed methodological description was discussed before (17), and the data collection period spanned from May 10, 2021 (27th Ramadan, 1442 Hijri) to June 10, 2021 (29th Shawwal, 1442 Hijri). Eligible participants were adult Muslims (≥ 18 years) practicing RIF in twenty countries. Exclusion criteria included a history of mental health issues and adherence to specific diets. A UAE-based research team initiated this study, employing snowball sampling for participant recruitment. Collaborators in various other regions disseminated the survey through digital platforms like email, WhatsApp, and Facebook. This strategy facilitated extensive questionnaire distribution, even amidst pandemic-related restrictions. Utilizing G*Power for one-tailed Student's t-tests and bivariate correlation, the study determined a sample size of 207 from each country based on an anticipated effect size of 0.2, alpha error of 0.05, and a power of 0.90 (18).

Conforming to the Declaration of Helsinki's ethical standards (19), ethical clearance was obtained from the Social Sciences Research Ethics Committee of the United Arab Emirates University, UAE (Approval number ERS 2021-7308) and Tehran University of Medical Sciences, Tehran, Iran (Approval number IR.TUMS.FNM.REC.1400.022). Participants gave informed consent, with no financial or non-financial incentives for participation. A comprehensive electronic questionnaire in eleven languages assessed demographics, dietary intake, eating habits, sleep, physical activity, computer use, and smoking during RIF. The translation adhered to established guidelines for accuracy and cultural relevance, including forward and backward translations and pilot testing with 30 participants (20).

Standardization of similar responses, exclusion of incomplete or non-fasting responses, and body mass index (BMI) calculation using World Health Organization (WHO) norms were part of data quality assurance. Abnormal or underage responses were also excluded. The questionnaire captured sociodemographic data, eating behavior, dietary diversity, weight changes, and health status before and during Ramadan. The collected sociodemographic information encompassed gender and age (in years), country of residence, nationality, region, marital status (single, married, divorced, or widow), residence area (city, town, or village), household income, living conditions (alone, with friends, or with family), educational level, the number of fasting days experienced, occupational status (employed or unemployed), work sector (private or government), father's and mother's level of education, total household income, classification of household income, living status before and during the month of Ramadan (alone or with family), personal and family history of obesity, diabetes, hypertension, cardiovascular diseases, and number of days of fasting during Ramadan.

Information regarding participants' dietary habits and modified eating practices since fasting, including

quality, quantity, types of products, and mealtime schedules, was obtained through questionnaires. The section on dietary diversity specifically probed adjustments made to common food groups, encompassing vegetables, fruits, cereals and grains, oils and fats, milk and milk products, pulses, dates, fish and seafood, low-fat meat (chicken and turkey), sugar, salty snacks, fried foods, carbonated or sugary drinks, energy drinks, hot beverages, pastries, homemade foods, traditional foods, and fast foods (21, 22). The frequency of ordering fast food and eating out before and during Ramadan was captured through a modified short food frequency questionnaire, tailored to align with prevalent dietary patterns in the country (22). Similarly, eating behaviors before and during the fasting month of Ramadan were assessed by asking participants about the daily quantity of water consumed, snacking habits, intake of large food quantities, and eating despite a lack of hunger (23).

Participants were requested to provide self-reported data on their current body weights (in kilograms) and heights (in centimeters), which were subsequently utilized to calculate their BMI (kg/m^2) during the analysis. The BMI values were then categorized into four groups of underweight (<18.5),

Table 1: Demographic characteristics of the study population.

Variable	Male	Female	Total
Sex	8175	13482	21657
Age (Years)

normal (18.5-24.9), overweight (25.0-29.9), and obese (>30). Additionally, respondents were inquired about their perceived weight status during Ramadan, categorizing it as lost, maintained, or gained. They were also asked to self-perceive their current weight status as normal, underweight, overweight, or obese. Furthermore, participants indicated the amount of weight perceived to have been lost (-1 to -4.5 or more), maintained (0), or gained (+1 to +4.5 or more) during Ramadan. The respondents were also prompted to evaluate their health status before and during Ramadan using a Likert scale (Poor, Fair, Good, Very good, and Excellent). This Likert scale was later condensed into poor or sound during the analysis.

Results

In this research, there were a total of 21,657 participants from twenty countries. Of the total participants, 62.2% (n=13,482) were females and 3.78% (n=8,175) were males. The age range of the participants was 18 years and older. Based on marital status, 71.3% (n=15,441) of participants were single. The participants were from the countries of Afghanistan (8.2%), Algeria (2.68%), Bahrain (2.93%), Bangladesh (4.33%), Egypt (9.55%), Indonesia (3.65%), Iran (13%), Iraq (4.93%), Jordan (2.71%), Kuwait (0.05%), Libya (3.42%), Morocco (6.05%), Pakistan (8.33%), Palestine (7.57%), Qatar (1.74%), Saudi Arabia (1.71%), Syria (5.38%), Tunisia (2.28%), UAE (14.67%), and Yemen (3.73%) (Table 1).

Table 2 shows the prevalence of underweight, overweight, and obesity in the studied twenty countries of this research. The prevalence of underweight, overweight, and obesity in twenty countries was equal to 9%, 25%, and 13%, respectively. Among the studied countries, the lowest prevalence of underweight was related to Afghanistan (2%), and the highest was associated with Yemen (15%). The lowest prevalence of overweight was linked to Iran (2%) and Algeria (2%), and the highest prevalence of overweight was related to Egypt (35%). The lowest prevalence of obesity was associated with Iran, Algeria, Palestine, Tunisia, and Yemen, with 8% prevalence, and the highest prevalence of obesity was related to the country of Bahrain, with 29% prevalence. Figure 1 and Figure 2 show the prevalence of normal weight, underweight, overweight, and obesity among associated demographic factors studied in this research.

Our results depicted that people with a family history of obesity had a higher prevalence of obesity and were overweight. People who did not have any physical activity during Ramadan, the prevalence of underweight, overweight, and obese was higher among such people when compared to those who did some physical activity. Underweight prevalence was higher among females (10.80%) than males (5.30%). At the same time, the prevalence of overweight and obesity was higher in males. People who were married or divorced/widow had more prevalence of overweight and obese than singles.

Table 2: Prevalence of underweight, overweight, and obesity in various countries.

Variable	Underweight% (CI)%	Overweight% (CI)%	Obesity% (CI)%
Total (20 countries)	09 (08-09)	25 (24-25)	13 (13-14)
Afghanistan	02 (01-06)	20 (15-27)	11 (07-16)

Saudi Arabia	10 (08-14)	23 (19-28)	18 (15-23)
Syria	10 (09-12)	22 (19-24)	15 (13-17)
Tunisia	05 (04-08)	23 (20-27)	08 (06-11)
United Arab Emirates	07 (07-08)	26 (25-28)	13 (12-14)
Yemen	15 (13-17)	22 (19-25)	08 (06-10)

Figure 1: Family history of obesity and weight changes.

Figure 2: Physical activity and weight changes.

The ratio of overweight and obese was higher in illiterate and individuals with less than a high school education. People who reported excellent, good, or very good health status had a more normal prevalence than other weight groups. At the same time, the prevalence of underweight was high with poor health.

This study aimed to analyze the effect of food consumption behavior, family history of diseases, physical activity, and dietary patterns on BMI during Ramadan.

Table 3 shows the role of demographic variables, family and personal history of diseases, and lifestyle components, including nutrition quality, smoking, and physical activity in underweight, overweight, and obese subjects. Multinomial logit model results indicated that the most significant variables for increasing risk of being underweight were being male, having a personal history of hypertension, having

poor health status, and having physical activity. The most influencing variables for increasing risk of overweight/obesity were marital status, personal history of tension, and poor diet quality.

Females had more relative risk of being underweight by 0.56 ($p < 0.01$) than males. Age was also positively and significantly related to underweight. Still, this relationship was more robust, while obese people in the upper age bracket had more risk of being obese by 7.9 ($p < 0.05$) than those who aged 18-32 years. A family history of obesity, diabetes, and high blood pressure was negatively related to weight level. Similarly, the personal history of obese was strongly and negatively associated with underweight as it lowered the relative risk of underweight by 0.43 ($p < 0.01$); but the risk of being overweight and obese decreased by only 0.07 and 0.02, respectively, and then those who had no personal history of obesity.

Table 3: Analysis of factors associated with underweight, overweight and obesity cases.

Personal history of hypertension was positively associated with the risk of being underweight by 1.30 ($p<0.05$) and overweight by 1.41 ($p<0.01$), but its relationship with obesity was not statistically significant. Good health status significantly reduced the relative risk of being overweight and obese by 0.86 ($p<0.05$) and 0.78 ($p<0.01$) when compared to those with excellent health status. Similarly, physical activity was negatively and significantly related to overweight and obesity. For people who continued

physical activity during Ramadan, their risk of being overweight decreased by 0.60-0.65 ($p<0.01$) than those who did not perform any physical activity; while the risk of being obese decreased by 0.60-0.80 ($p<0.01$). Finally, smoking and personal history of diabetes were not significantly related to weight.

Table 4 presents factors like modified consumption of fruits, vegetables, fried food, oil fats, milk and tea, pulses, meat, snacks, dates, etc.

Table 4: Analysis of diet factors in relation to underweight, overweight, and obese cases during Ramadan.

Moreover, a weight comparison was also performed among homemade and delivery food consumers. Table 4 reveals the relative risk ratio for the model of underweight, overweight, and obese, while normal weight was a base category. The results in Table 4 show that the relative risk of being obese increased by 2.31 ($p<0.01$) with the decrease in fruits during the study period in comparison to those who did not consume fruits during Ramadan; but the risk of being overweight decreased by 0.88 ($p<0.01$) with the increase in consumption of fruits. The relative risk of being overweight and obese also increased by 1.29 ($p<0.01$) and 1.45 ($p<0.01$), respectively, among those who improved the consumption of fried foods. Consumption of more vegetables decreased the relative risk of obesity as our findings demonstrated that an increase in consumption of vegetables significantly reduced the relative risk of obesity by 0.78 ($p<0.01$) and underweight by 0.50 ($p<0.01$) than the base group. Similarly, cereal food items also declined the risk of overweight and obesity by 0.48 ($p<0.01$) and 0.78 ($p<0.01$), respectively, as the consumption of cereal food items maintained the body mass and lowered the chances of obesity and weight gain.

Consumption of oil and fat could also significantly affect weight. A decrease in the consumption of oil fats during the month of Ramadan could reduce the relative risk of obesity by 0.56 ($p<0.01$), but it was inversely related to being overweight. The consumption of pulses was positively and significantly associated with weight. The relative risk of overweight decreased by 0.74 ($p<0.01$) in those who reduced the consumption of pulses during Ramadan. In contrast, the risk of obesity increased by 1.24 ($p<0.01$) in those with improved pulse consumption. Dates were also high-calorie food, which was commonly consumed during Ramadan. So, it has an inconclusive relationship with the weight of people. However, the relative risk of obesity increased among those who consumed more dates or maintain consumption according to everyday routine life. Chicken consumption was

also not harmful to body weight, and the decrease or increase in its consumption did not create any obesity or underweight condition. An increase in consumption of chicken could decrease the relative risk of obesity by 0.60, and a decrease in its consumption lowered the risk of obesity by 0.76 ($p<0.01$) and underweight by 0.78 ($p<0.01$).

Excessive sugar was harmful to health as it increased the risk of obesity by 2.22 and lowered the risk of being underweight by 0.73 ($p<0.01$). People who consumed sugar in Ramadan either decreased its consumption, while the relative risk of being malnourished and overweight decreased between 0.76 and 0.78 ($p<0.01$); but increased the ratio of obesity by 2.51 ($p<0.01$). An increase in the consumption of salty snacks could lower the relative risk of being underweight by 0.80 ($p<0.01$) and increased the risk of obese by 1.41 ($p<0.01$). Tea and coffee illustrated irregular patterns with weight gain and loss. For people who drank more tea in Ramadan after intake of food (Aftar) or remained in their usual routine, the risk of being overweight increased by 1.40 ($p<0.01$). However, it lowered the risk of obesity as it was consumed after food to control the appetite. During Ramadan, people made various items at home to consume during Aftar, but it did not affect their weight too much. Results of our study also revealed that consumption of homemade food items declined the risk of being overweight, underweight, and obese. Still, delivery items increased the risk of being overweight; either these increase or decrease.

Discussion

This study was conducted on more than 21,500 adults from around the globe to analyze the observed nutritional patterns on BMI during Ramadan. The study highlighted the heterogeneous patterns in food consumption behavior during Ramadan. Our results showed that the most significant factors preventing underweight were consuming vegetables, fruits, cereal foods, chicken and turkey meats, and homemade food items. The

most important risk factors for being overweight were consumption of meat, fried foods, oil fats, milk, delivery foods and frequently drinking of carbonated beverages, tea and coffee. In contrast, obesity risk factors were consumption of carbonated drinks, tea, coffee, meat, sugar, dates, pulses, fried foods, and fruits. In the month of Ramadan and lockdown, some people consumed unhealthy food items, which were responsible for obesity and were negatively associated with being underweight (24). Vegetables and fruits are considered as essential and low-calorie items to maintain body weight through regular physical activity. An increase in the intake of fruits and vegetables helps control blood pressure and helps control being overweight. But, if physical activity is not managed with the increased consumption of such items, it can lead to obesity (25).

Cereal food items can also lower the risk of overweight and obesity as these items contain balanced nutrients like fiber and minerals. However, excessive consumption of cereals such as sugar can result in an imbalance of weight and can cause obesity or unhealthy weight loss when associated with other diseases like diabetes. People who consume excessive amounts of fried food items in the Ramadan were reported to be overweight and obese as it contains excessive oil fats, while during the month of Ramadan, the physical activities become much lower. Therefore, successive use of fried foods affects the metabolism, increases empty calories and thus results in weight gain and obesity (26). The relationship between weight and salty snacks is complex. Some people consume high-caloric snacks in Ramadan, including crackers, potatoes, and pretzels, which increases the risk of obesity and overweight. However, some snacks with lower calories do not contain nutrients like fiber and vitamins, which can be used to control diet and weight balance. One of the significant findings of our study included homemade food items that helped prevent underweight, overweight, and obesity conditions. Diversified food patterns cooked at home were shown to lower the risk of overweight and obesity (27).

Our results also showed that married people had a high risk of being overweight and obese. This might be why married people change their life patterns by sharing meals, frequently sitting together for a meal outside, or social gatherings. However, a healthier lifestyle and physical activities can reduce the risk of weight gain and weight loss. Moreover, age is positively related to BMI classification among the demographic characteristics (28). Age doesn't always have to be related to weight gain or loss. It is indirectly

associated with other factors like physician activity, nutrient intake, consumption pattern of food items, and health status. Good health status lowers the risk of being underweight, overweight, and obese in all ages (29, 30). Previous studies also highlighted the importance of physical activities in weight loss and controlling obesity. Aerobic or any physical activity of 5-120 mins a week helps maintain good health and weight loss in the prevalence of overweight and obesity (31).

Conclusion

People who take care of their dietary patterns were shown to have a low risk of being underweight, overweight, or obese. Maintaining food patterns by Muslims during Ramadan requires cautious nutritional habits and choices. This research provided practical implications for supporting healthy food patterns during Ramadan to avoid health consequences. Muslim communities can encourage and start group walks, physical activities, and a few fitness classes to help burn excessive calories. A social media campaign about nutritional guidelines that guide calorie intake after sunset and sunrise time can also be launched. Religious scholars can also be involved in this matter on a platform through social media to encourage healthy food intake and adopt healthy practices.

Acknowledgement

None.

Funding

This research received no external funding.

Authors' Contribution

The study was conceptualized by SA and MAK. Formal analysis was conducted by HD. The original draft of the manuscript was prepared by RAF, AA, HD, MF, SA, and MAK. Review and editing of the manuscript were carried out by SA, MAK, and HD. Project administration and supervision were performed by MAK, SA, and HD.

Conflict of Interest

None declared.
